Endogenous Leadership in a Federal Transfer Game

Bodhisattva Sengupta*

This version: March 15, 2017

Abstract

Conventional wisdom suggests that, to negate fiscal externalities imposed by provinces which spend too much and raise lower local resources, central authority should always be a first mover in the transfer game. In spite of such recommendations, central governments, in almost all countries, chooses to be the second mover from time to time. We explore the conditions, other than the familiar political economy arguments, under which the central government optimally chooses to be the second mover. Moreover, ex post transfer protocols may induce provinces to generate more local resources than otherwise. The results depend crucially upon the benefit received by each level of government from the project outcomes of other tier.

Key words: Federalism, Transfer Game, First and Second Mover Advantages

*Department of HSS, IIT-Guwahati, Assam, India 781039. E-Mail: bsen-gupta@iitg.ernet.in; Phone: +91-361-258-2575.
1 Introduction

In this paper, we attempt to answer the following set of questions: in order to maximize its benefit, should a central government in a federal economy choose to make *ex-post* grants (disbursed after the provinces make their tax-expenditure decision) to provinces? Or should it commit to an *ex-ante* transfer and try to control provincial action? Why does the former behavior persist in real world in spite of the fact that recent intellectual paradigm favors the latter?

Due to inherent vertical and horizontal imbalances in a federal economy, central (or federal) authority has to transfer funds to provinces. A point of concern is the degree of control wielded by the central government over the subnational units regarding disbursement and utilization of such funds. In absence of any credible central commitment towards transfer, provinces will face a soft budget constraints: resulting into higher subnational public expenditure and subsequent bail out. At best, it will reduce fiscal space of the centre. At worst, this may lead the whole country to macroeconomic imbalance (e.g. Brazil or Argentina in 1990’s).

As already noted, recent policy prescriptions are heavily biased to hard budgets. Anwer Shah (2006, p 47), for example, prescribes that "Grants to finance subnational deficits, which create incentives for running higher deficit in future" are to be avoided. In India, the Twelfth Finance Commission, a constitutional body which regulates centre state financial relation to a large extent, had recommended (2004) the termination of central governments’ role in assuming the states’ debt. In other words, centre should dispense with the *ex post* grants.

In spite of this intellectual onslaught, bailout by centre (which is, almost and always, *ex post* in nature) still persists, ostensibly, in name of equity. One can argue that such transfers are inherently politically motivated,\(^\dagger\)

\(^\dagger\)Evidence of political motivation behind *ex post* grants, either partisan or strategic, is well documented in, say, Solé-Ollé and Sorribas-Navarro (2008) in Spanish municipal
so centre always bails out electorally important provinces. Alternatively, bailouts can be constitutional obligation of central government. What we attempt in this paper is to explain constitutional persistence of such allegedly inefficient behavior from efficiency calculations. Due to sequential nature of grant dispensation in a federation, the cost-benefit calculus (of ex post vis-à-vis ex ante) should be done in a sequential game framework, in which the provinces and the centre are the two sets of players. Depending on the nature of the game, it is possible that there exists a second movers advantage that the centre wishes to exploit. The basic assumption is centre acting as a dictator, writes the fiscal constitution in order to maximize federal welfare. If it happens that the centre maximizes its welfare by being a second mover in the grant dispensation game, constitution must have a provision for soft budgets and bailouts.

To formalize the trade-off facing a central government, we assume that centre has a fixed fund (obtained through income taxation) which finances a central project as well as transfer to provinces. Transfers are earmarked for provincial projects. Each level of government value outcome of the project at the other sphere. Under this set up, we show that there is a possibility of second movers’ advantage for the central government. The result depends on the degree to which central project benefits provinces. If the benefit is high, then centre is better off by being a second mover. On the other hand, if the link between central project and provincial welfare is small or non-existent, center is better off being a first mover. As a policy prescription, our suggestion is that there is little room for "one-size-fits-all" type of transfer protocol. Rather, such transfer protocols are to be based on the nature of central project.

The paper is organized in the following way. Section 2 presents relevant literature. Section 3 describes the basic model. Section 4 characterizes different equilibria that may arise. Section 5 provides a discussion on elections or Arulampalam et. al. (2008) in discretionary funding to states in India.

---

2E.g. as in German constitution. See Rodden (2006)
endogeneity of different constitutional protocols in the context. Section 6 compares the protocols in terms of central transfer, provincial taxation and project outcomes at two levels of government. Section 7 concludes.

2 Literature

Since the formation of EU, literature has proliferated in the so called "decentralized leadership" problem, solely devoted to the problem of achieving efficiency in a federation with province as the leader. For example, in Wildasin (2001), bailouts (of big provinces) are rationalized in presence of (environmental) spillover. In Goodspeed's (2002) treatment, a politically motivated centre bails out provinces in order to reduce provincial dependence on borrowing. In a world where provinces compete for mobile capital and central government transfers funds ex post, Koethenbuerger (2004) demonstrates that welfare can increase as central transfer restrainsthe 'race to the bottom'. Akai and Sato (2008) investigate the problem of inefficiency under different fiscal regimes. Silva (2015) investigated efficiency of decentralized leadership under various assumptions on mobility of capital and labor as well as the transfer tools of the federal government (fiscal and/or income).4

In the cited works (except Akai and Sato, ibid), however, there is no alternate use of central fund other than operating either a gross or net equalization scheme.5 In our opinion, this misses a crucial aspect of federal economies: that apart from financing transfer to provinces, a considerable

---

3The term was coined by Silva and Caplan (1997).
4From a different perspective, Besfamille and Lockwood (2008) have explored the relative inefficiency of hard budgets. A key tool for their analysis is imperfect information and the associated moral hazard problem. Provincial revenue raising activities are not observable by the central authority. In real life, however, due to availability of budgetary documents in public domain and continuous scrutiny by media, such an assumption is hard to maintain.
5For Akai and Sato, however, the sole ‘alternate’ use is providing a national public good. Our formulation differs here.
part of central budget is used by higher level government for finance its own project. For example, in Canada, during 2014-15, total transfer to provinces was 22% of federal revenue collection. Likewise, in Australia, the 2012-13 shares of states in federal revenue were approximately 24%. In India, the Fourteenth Finance Commission recommended that 42% of central taxes be transferred to the states.\(^6\) This element of reality has two implications in modeling. First, the central social welfare function would be non-Benthamite in nature. Second, once we allow for a central project net of transfer, it is possible that provinces also benefit from a central project.

To the extent that provinces derive utility from central transfer (to provincial projects) as well as central project, there is a trade off with higher transfer both at provincial as well as central levels. This trade-off implies that the project at one level can be plain (or strategic) complement (or substitute) to the other level.\(^7\) Such a relation between different projects leads naturally to endogeneity of moves in a Stackelberg game. Methodologically, our paper is closer to Kemph and Graziosi (2010). In this paper, the authors address the issue of leadership between countries with transboundary externalities (e.g. environmental externalities) in a perfect information set up. However, the emphasis is on the interaction between countries, not between hierarchical governments, which is a feature of federal economies.

In sum, there are two different strands of literature within fiscal federalism regarding commitment. One preoccupies itself with the consequences of different commitment protocols within a federation with hierarchical governments, but assumes utilitarian central government. To the extent central government is non utilitarian, it is assumed to act out of political compulsion (e.g, Goodspeed, \textit{ibid}). We complement the literature by assuming a non-utilitarian central government, operating in a perfect information set up.

\(^6\)These data are accessible from the Government websites of different countries. For Australia: www.budget.gov.au/2012-13, for Canada: www.fin.gc.ca, and for India: finco-mindia.nic.in.
\(^7\)The terminology comes from Eaton (2004). For definitions, refer to appendix A1.
without relying on the assumption of political motivation.

3 Model

We assume a simple federal set up consisting of centre and two provinces \((i = 1, 2)\). Provinces derive utility from a local project (outcome \(p_i\)) and local consumption \((c_i\), which equals net income after taxes\). Central authority benefits from a central project (outcome \(P\)). In addition, both central and provincial projects are valued by other tiers of government. Centre faces a budget constraint: \(P + T_1 + T_2 = M\), where \(T_i\) is the transfer made to province \(i\). \(M\), the total amount of central fund, is exogenous.

Provincial welfare is

\[
w^i(p_i, c_i; P) = u(p_i) + v(c_i) + \beta f(P)
\]

\(f(.)\) represents provincial benefit from central project. The parameter \(\beta\) is the weight (or, equivalently, a parameter that captures marginal/total benefit) that a province puts on benefit from central project. Different values of \(\beta\) and different forms of \(f\) allow us to capture many facets of reality.\(^8\)

Similarly, central welfare depends on \(p_i\) and \(P\):

\[
W(p_1, p_2, P) = V(P) + \gamma(F(p_1) + F(p_2))
\]

Here, \(V\) is the benefit that centre receives from own project. \(F(.)\) is the benefit that the centre receives from provincial project and \(\gamma\) is the weight on associated benefits (equivalently, a parameter characterizing marginal benefit).\(^9\) Again, this formulation allows us to capture many facets of reality. To focus on the hierarchical behavior of centre and provinces, we assume away

\(^8\)If \(P\) is armament import, provinces may perceive that the benefit is close to 0. If \(P\) is federally sponsored road network, \(\beta\) could be quite high. There is no upper limit on \(\beta\).

\(^9\)Traditionally, in Fiscal Federalism literature, centre is seen as a Benevolent dictator which has sum of provincial utilities as objective function. In the present formulation, the extent to which Central government cares for provinces is captured by the \(\gamma \sum F_i(.)\) term. It may be noted that such non-Benthamite formulation of Federal welfare is not
inter-provincial benefit from \( p_i \). We also make the familiar assumptions:
\( u', v', V', f', F' > 0 \) and \( u'', v'', V'', f'', F'' < 0 \). As mentioned in section 1, a further assumption is the center has an overriding presence, such that its best interest is will be protected in the constitution and institutionalized.

We assume that provinces are identical (save in income endowment, \( y_i \)). We need this assumption in order to induce identical transfer protocols for both provinces, i.e. if centre is leader (follower) with respect to one province, it can not behave differently towards other province.

4 Characterizing Equilibrium Protocols

Now we put more structure to the model by explicitly bringing in the nature of central grants. Grants are conditional in the sense that these are tied to a specific provincial project. Province raises a tax, say \( \theta_i \), to finance the public good project. Centre provides the transfer \( T_i \) to province \( i \) such that \( T_1 + T_2 + P = M \). Provincial public good is \( p = \theta_i + T_i \). Provincial consumption is \( c_i = y_i - \theta_i \).\(^{10}\) Incorporating these information in the utility functions, we can write (1) and (2) as functions of \( \theta_i \) and \( T_i \)’s, where \( i = 1, 2 \).

without precedence, e.g. see Snowdon and Wen (2003). In their formulation, provincial cost reduces centres’ welfare. In our formulation, provincial project outcome increases central benefit.

Further, one may argue that the central objective function is
\[ W = V(P) + \delta \sum [u'(p_i) + v(c_i)] \] \(^{(A)}\)

A problem with \((A)\) the first best solution (in which the centre can choose both \( \theta_i \) and \( T_i \)) and the Nash outcome coincide. In other words, there is no overall reason for the constitution to accomodate hierarchical moves in grant dispensation.

\(^{10}\)It is possible that central fund depends on federal income tax, i.e. \( M = \tau (y_1 + y_2) \), where \( \tau \) is the rate of tax and \( c_i = (1 - \tau) y_i - \theta_i \). This will not change our results, as long as \( \tau \) is exogenously given. We assume away from the issue.
4.1 Reaction Functions

Province $i$ chooses $\theta_i$ to maximize\(^{11}\)

$$w(\theta_i, T_1, T_2) = u(\theta_i + T_i) + v(y_i - \theta_i) + \beta f(M - T_1 - T_2) \quad (3)$$

From the first order condition,

$$u'(\theta_i + T_i) = v'(y_i - \theta_i) \quad (4)$$

The slope of provincial reaction function is

$$\theta'(T_i) = -\frac{u''}{u'' + v''} < 0 \quad (5)$$

Thus $T_i$ is strategic substitute for $\theta_i$. Since raising $\theta_i$ is costly for the province, higher $T_i$ will reduce $\theta_i$. Note that $\frac{\partial \theta_i}{\partial T_i} = \frac{u''}{u'' + v''} > 0$ on the reaction function of the province.

Similarly, centre chooses $T_1, T_2$ to maximize\(^{12}\)

$$W(T_1, T_2, \theta_1, \theta_2) = V(M - T_1 - T_2) + \gamma [F(\theta_1 + T_1) + F(\theta_2 + T_2)] \quad (6)$$

The first order conditions are, for $i = 1, 2$

$$-V'(M - T_1 - T_2) + \gamma F'(\theta_i + T_i) = 0 \quad (7)$$

From the first order conditions, we can express the reaction function of centre as $T_i(\theta_1, \theta_2)$. It can be shown that

$$\frac{\partial T_i}{\partial \theta_i} = -\frac{\gamma F'' (V'' + \gamma F'')}{(V'' + \gamma F'')^2 - (V'')^2} < 0 \quad (8)$$

$$\frac{\partial T_j}{\partial \theta_i} = \frac{\gamma F'' V''}{(V'' + \gamma F'')^2 - (V'')^2} > 0 \quad$$

\(^{11}\)It can be shown that the associated Hessian matrix is negative definite (irrespective of the value of $\beta$). Thus the problem of non convexity does not arise.

\(^{12}\)We cannot assume the benefits from provinces to be $F(p_1 + p_2) = F(\sum(\theta_i + T_i))$ since that would leave transfer to individual provinces $(T_i)$ indeterminate.
Similarly for $\theta_j$. Thus, an increase in $\theta_i$ will reduce $T_i$ but increase $T_j$. Notice that, following an increase in $\theta_i$, the sum $(T_1 + T_2)$ falls, and hence an increase in provincial taxation reduces total central transfer and *quid pro quo*, increases output from central project on the reaction function of centre.

The slope of central reaction function is *negative* on $T_i - \theta_i$ plane. The reason is as follows. Higher $T_i$ is costly for the centre (as its own public good production decreases). At the same time, with higher provincial taxation, provincial welfare from public good will increase. Since centre cares for the provincial public good, $(\gamma \neq 0)$ centre’s response is to reduce the transfer as $\theta_i$ increases.

**Example 4.1** Let $u(\cdot) = p_i - \frac{\delta}{2}p_i^2$, $v(\cdot) = c_i - \frac{\rho}{2}c_i^2$, $f(\cdot) = P - \frac{\lambda}{2}P^2$, $V(\cdot) = P - \frac{\eta}{2}P^2$; $F(\cdot) = p_i - \frac{\phi}{2}p_i^2$. We assume that the parameters $\delta, \rho, \lambda, \eta, \phi$ are small enough to always guarantee positive marginal utility.

For province $i$, the FOC is

$$1 - \delta(\theta_i + T_i) = 1 - \rho(y_i - \theta_i)$$

$$\implies \theta_i(T_i) = \frac{\rho y_i - \delta T_i}{\delta + \rho}$$

For centre, the FOC’s are

$$-1 + \eta(M - T_1 - T_2) + \gamma(1 - \phi(\theta_1 + T_1)) = 0$$
$$-1 + \eta(M - T_1 - T_2) + \gamma(1 - \phi(\theta_2 + T_2)) = 0$$

Solving this, we get

$$T_i(\theta_i, \theta_j) = \frac{\gamma + M\eta - 1}{2\eta + \gamma\phi} - \frac{\eta + \gamma\phi}{2\eta + \gamma\phi} \theta_i + \frac{\eta}{2\eta + \gamma\phi} \theta_j$$

On central reaction function, total transfer is $T_1 + T_2 = \frac{2(\gamma + M\eta - 1)}{2\eta + \gamma\phi} - \frac{\gamma\phi}{2\eta + \gamma\phi} (\theta_1 + \theta_2)$

---

13Higher $\theta_j$ will ‘blow’ the reaction function to right.
Outcome of central project \( P = \frac{M \gamma \phi + 2(1 - \gamma)}{2\eta + \gamma \phi} + \frac{\gamma \phi}{2\eta + \gamma \phi} (\theta_1 + \theta_2) \)

The structure of the problem allows us to treat interaction between different provinces and centre separately. For example, the reaction functions of centre and province \( i \) can be plotted in the \( \theta_i - T_i \) plane, keeping \( \theta_j \) as a parameter, which is determined in the \( \theta_j - T_j \) plane.

4.2 Nash Protocol

The Nash outcome \( (\theta_1^N, \theta_2^N, T_1^N, T_2^N) \) is solution of the following equations:

\[
\frac{\partial w(\theta_i^N, T_1^N, T_2^N)}{\partial \theta_i} = 0; \ i = 1, 2 \tag{9}
\]

\[
\frac{\partial W(T_1^N, T_2^N, \theta_1^N, \theta_2^N)}{\partial T_i} = 0; \ i = 1, 2
\]

As it is clearly demonstrated, we have a Cournot type game with downward sloping reaction functions.

It can be shown that the equilibrium is stable. A Nash outcome is more likely if neither provinces, nor centre are able to commit or reach a binding,
enforceable constitution.

### 4.3 Stackelberg Protocols(s)

Here, we define the problems first.

If centre is the first mover, then it chooses $T_1$ and $T_2$ in such a way that

$$W(T_1, T_2) = V(M - T_1 - T_2) + \gamma [F(\theta_1(T_1) + T_1) + F(\theta_2(T_2) + T_2)]$$

is a maximum. Here, $\theta_i(T_i)$ is the reaction function of the province (obtained from 4).

In symbols, the first order condition at the optimum can be written as, for $i = 1, 2$

$$\frac{\partial W(\theta^F_1, \theta^F_2, T^L_1, T^L_2)}{\partial T_i} + \frac{\partial W(\theta^F_1, \theta^F_2, T^L_1, T^L_2)}{\partial \theta_i} \frac{\partial \theta_i}{\partial T_i} = 0 \quad (10)$$

Solution to two equations will yield $T^L_i$. Plugging into provincial reaction functions, we get $\theta^F_i$.

We show how $\gamma$ alters $T_i$. In order to demonstrate the result, we continue with the LQ example.\(^{14}\)

**Lemma 4.1** If $\gamma$ increases, then $T^L_i$ increases. As a result, $P^L$ falls and $p^F_i$ increases.

**Proof.** See appendix A2. ■

If $\gamma$ increases, then centre places lower weight on its own project and higher weight on provincial projects. Hence transfers increase.

If province $i$ (given the symmetry of provinces, similar conditions can be derived for province $j$) is leader vis-a-vis the centre, then it has to choose $\theta_i$ in such a way that

\(^{14}\)If we do not assume LQ functional form, then, in the comparative statics analysis, second derivatives of the reaction function such as $\frac{\partial^2 \theta_i}{\partial T_i^2}$ etc. involve third derivatives of the utility functions. This becomes difficult to interpret.
\[ w^i = u(\theta_i + T_i(\theta_1, \theta_2)) + v(y - \theta_i) + \beta f(M - T_1(\theta_1, \theta_2) - T_2(\theta_1, \theta_2)) \]

is a maximum. Here, \( T_i(\theta_i, \theta_j) \) is the reaction function of the centre (obtained from equation 7).

In symbols, the first order condition can be written as, for \( i = 1, 2 \)

\[
\frac{\partial w^i(\theta_1^L, \theta_2^L, T_1^F, T_2^F)}{\partial \theta_i} + \sum_{j=1,2} \left[ \frac{\partial w(\theta_1^L, \theta_2^L, T_1^F, T_2^F)}{\partial T_j} \right] \frac{\partial T_j}{\partial \theta_i} = 0 \quad (11)
\]

Solutions to above equations will yield \( \theta_i = \Theta^j(\theta_j) \) and \( \theta_j = \Theta^i(\theta_i) \). Since our main concern is hierarchical structure between the centre and provinces, we refrain from inter provincial commitment issues that may arise when provinces are first mover. That is, \( (\theta_1^L, \theta_2^L) \) is determined by a simultaneous move game. Continuing with the LQ example, we prove a couple of lemmas to characterize provincial interaction. We focus on the parameter \( \beta \) because it takes a central stage in our model.

**Lemma 4.2** If \( \beta \) is sufficiently high, then \( \theta_1, \theta_2 \) are strategic substitutes in the simultaneous move game.

Note that, if \( f(.) = M - T_1 - T_2 \) so that the second derivative is zero, then \( \theta_1 \) and \( \theta_2 \) are always strategic complements.

**Lemma 4.3** If \( \beta \) increases, then equilibrium \( \theta_i^L \) increases.

**Proof.** See appendix A2. ■

It can be shown that the partial effect of \( \beta \) on \( \theta_i \left( \frac{\partial \theta_i}{\partial \beta} \right) \) is positive. In case of strategic complementarity between \( \theta_1 \) and \( \theta_2 \), the total effect of \( \beta \) on \( \theta_i \) (consisting of the partial effect as well as the indirect effect via \( \theta_j \)) is unambiguously positive. In case of strategic substitutability between \( \theta_i \) and \( \theta_j \), the total effect is potentially ambiguous. However, as the above lemma proves, the effect is also positive.
5 Determination of Outcomes

To determine the first and/or the second movers’ advantage in the Stackelberg game, we need to figure out the shape of iso-welfare curves of the province as well as the centre. That is, we need to determine whether the strategic variables chosen by different tiers of government are plain substitutes/complements.

5.1 Provincial Iso-welfare Curves

Let us first look at the provinces. The iso-welfare curve is defined by

$$\bar{w}_i = u(\theta_i + T_i) + v(y_i - \theta_i) + \beta f(M - T_1 - T_2)$$  \hspace{1cm} (12)

The slope of the curve in the $\theta_i - T_i$ plane\(^{15}\) is $\frac{dT}{d\theta} \bigg|_{\bar{w}} = -\frac{w_T}{w_T}$ and $\frac{d^2T}{d\theta^2} \bigg|_{\bar{w}} = -\frac{w_{\theta\theta}}{w_T}$ on the reaction function of province. Therefore, $\text{sign} \left( \frac{d^2T}{d\theta^2} \bigg|_{\bar{w}} \right) = \text{sign} (w_T)$ at the critical point. Now $w_T = u'(p) - \beta f'(P)$. Theoretically, higher central transfer leads to higher output from provincial project, but the amount spent on central output reduces quid-pro-quo, and hence there is loss of provincial utility. For low values of $\beta(\approx 0)$, higher $T$ is likely to be associated with higher provincial welfare. Hence $T$ is plain complement (PC)\(^{16}\) for province and the iso-welfare curves achieve a minimum on the reaction function. On the other hand, if $\beta$ is sufficiently high, then the provincial iso-welfare curves achieve a maximum on the reaction functions, and higher $T$ is associated with lower provincial welfare.

Example 5.1 Let us illustrate the point using the LQ specification. We have $w_T = 1 - \delta p - \beta(1 - \lambda P)$. Suppose $\lambda = 0$. Then, $T_i$ will always be a plain substitute (resp. complement) for province $i$ if $\beta$ is close to 1 (resp. 0).

\(^{15}\)So as to avoid division by zero. We have also removed subscripts to retain notational clarity.

\(^{16}\)See appendix A
5.2 Central Iso-welfare Curves

The Central Iso Welfare curve in $\theta_i - T_i$ plane is defined by the following equation

$$\bar{W} = V(M - T_1 - T_2) + \gamma [F(\theta_1 + T_1) + F(\theta_2 + T_2)]$$

Following logic similar to above subsection, we find that, on the central reaction function facing province $i$, $\frac{d^2\theta}{dT^2}|\bar{W} = -\frac{W_{TT}}{W_\theta}$, such that $\text{sign} \left( \frac{d^2\theta}{dT^2}|\bar{W} \right) = \text{sign} (W_\theta)$. Now $W_\theta = \gamma F'(\cdot) > 0$. hence $W_\theta > 0$. i.e. the central iso-welfare curve always has a minimum on the reaction function of the centre and higher $\theta$ implies higher welfare for centre (provincial tax is always a plain complement for centre). This is depicted in the following diagram.

5.3 Second Movers’ Advantage

Now we are ready to state our main proposition.

**Proposition 5.1** Assume that central grants are targeted to a specific provincial project. If the weight attached to central good by the provinces $(\beta)$ is sufficiently high, then central transfer is plain substitute for the province. As a result, centre is better off as a second mover. Otherwise, centre is better off as a first mover.

**Proof.** See appendix B. ■

This discussion can be summarized in the following diagram:
Figure 2: Centre Gains as Second Mover if $W_\theta > 0$ and $w_T < 0$

Note that, given $W_\theta > 0$, centre wish to settle for $\theta$ as high as possible. It is evident that, if $\beta$ is low, the provincial authority would like to have a high central transfer-low provincial taxes regime (because the cost of public good can be effectively shifted to the centre and it does not depend on central public good so much). In that case, centre gains by being the first mover and restrict the transfer.

6 Comparison: Central and Provincial Leadership

Here we compare the two equilibria in terms of project outcomes and transfers. Assuming similar provinces, provincial taxes are identical and can be represented by a common notation $\theta$. Similarly, central transfer, in equilibrium, will be same for both provinces and can be denoted by a generic $T$. Let the three equilibria (Nash, and two Stackelberg points) be given by $\langle \theta^N, T^N \rangle$, $\langle \theta^F, T^L \rangle$ and $\langle \theta^L, T^F \rangle$, respectively. We now have the following proposition.
Proposition 6.1  (i) Assume \( w_T > 0 \). Then, \( \theta^F > \theta^N > \theta^L \) and \( T^N > T^L \).

(ii) If \( \beta \) is large enough, such that \( w_T < 0 \). then \( \theta^L > \theta^F > \theta^N \) and \( T^F > T^L > T^N \) with the LQ example.

Proof. See appendix B. ■

As a corollary, we immediately have the following, for small \( \beta \) (when the constitutional outcome is centre as first mover)

Corollary 6.1  (ai) Central transfers are lowest when centre is a leader. That is, central project has highest output when centre is leader: \( P^L > P^F \).

(aii) Central leadership point is associated with highest provincial taxes, that is \( \theta^F > \theta^L \).

The effect on provincial public good, however, is ambiguous. As \( T \) decreases from \( T^F \) to \( T^N \), \( \theta \) increases along the central reaction function. Since the marginal response is more than 1, output of provincial project increases, \( p^N > p^L \). As \( T \) further decreases from \( T^N \) to \( T^L \), \( \theta \) increases along the provincial reaction function. However, the marginal response is less than 1, which means lower provincial public good. The ultimate effect will depend on (given the slope of reaction functions), the relative distances between \( T^F, T^N \) and \( T^L \).

The next corollary establishes the fact that with sufficiently high \( \beta \),

Corollary 6.2  (bi) Central transfers are higher with centre as second mover (that is \( T^F > T^L \)). As a result, central project yields lower output \( (P^F < P^L) \) in such cases.

(bii) Provincial tax efforts are higher when provinces are leaders \( \theta^L > \theta^F \). Thus \( p^L > p^F \).

Of particular interest is the result (bii) of corollary 5.2. We know that, with sufficiently high \( \beta \), centre is a second mover in the game. Thus, both provincial revenue and outcome of provincial projects are higher when centre
optimally chooses not to precommit, vis-à-vis the case when centre commits to the transfer.

7 Conclusion

In this paper, we have provided a general scenario under which the central government gains by limiting its power of commitment in the grant dispensation game within a federation. If central government grant is tied up with the public project of the province, provincial tax and central transfer are strategic substitutes. Higher central transfer lowers the marginal utility of public project to the province and province responds by cutting down taxes. Higher central transfer increases provincial welfare, but decreases output from central project. In case provinces attach high weight on central project, higher central transfer will reduce provincial welfare. In that case, provinces respond by increasing their own taxes. If central welfare is increasing in provincial taxes, then centre should choose a mode of transfer which generates higher provincial taxes. Thus, contrary to the Hamiltonian paradigm, provincial taxes can be higher even if central government is unable to commit.

The work can be extended to several dimensions. First, we have demonstrated the result with one type of grant. In a federal economy, the grants may just augment provincial budget instead of being tied to a project. It would be interesting to extend the result to such grants. Second, a key assumption of the paper is centre has an over-riding presence in dictating the mode of transfer. In many economies, the balance of power between centre and provinces are determined by bargaining, e.g. during nascent years of the USA. This opens up the possibility of a timing game to resolve the tie of leader/follower. Third, we have assumed that \( \beta \) for each province is same. But suppose it is not: some provinces, due to political alignment with centre, has a high \( \beta \), other provinces perceive \( \beta \) to be quite low. Then centre may be a first (second) mover with the latter (former)
group of provinces: we would expect provincial debt services being assumed by the central government in the politically aligned provinces. This suggests the familiar spectre of partisan behavior. But such partisan effect does not arise from centre putting different weight on provincial welfare, (as assumed in traditional political economy literature, e.g. Sengupta 2011), but from provinces placing different weights on central project.

Thus there exists future scope of research based on the current work.

Appendix A
Strategic and Plain Complements

Briefly, suppose $\pi^i(a_i, a_j)$ is benefit function for agent $i$, while $a_i$ and $a_j$ are own actions and other agents’ action, respectively. Then $a_j$ is plain complement (PC) for agent $i$ if $\frac{\partial \pi^i}{\partial a_j} > 0$, and plain substitutes (PS) if $\frac{\partial \pi^i}{\partial a_j} < 0$. Similarly, $a_i$ and $a_j$ are strategic substitutes (SS) (complements, SC) if $\frac{\partial^2 \pi^i}{\partial a_i \partial a_j} < (>) 0$. Similarly for agent $j$.

The first order condition for agent $i$ is

$$\frac{\partial \pi^i}{\partial a_i} = 0$$

Differentiating with respect to $a_j$, we have

$$\frac{\partial^2 \pi^i}{\partial a_i^2} \frac{da_i}{da_j} + \frac{\partial^2 \pi^i}{\partial a_i \partial a_j} = 0$$

$$\rightarrow \frac{da_i}{da_j} = -\frac{\frac{\partial^2 \pi^i}{\partial a_i \partial a_j}}{\frac{\partial^2 \pi^i}{\partial a_i^2}}$$

If SOC holds, the sign of cross (double) derivative determines the slope of reaction functions. In the same vein, sign of cross(singl)e derivative determine the shape of isoprofit curves near the reaction function.

Let the isoprofit curve for agent $i$ in $a_i - a_j$ plane be $\pi^i(a_i, a_j) = k$. The slope is

$$\frac{da_j}{da_i} = -\frac{\pi^i_i}{\pi^i_j}.$$  

Here, the lower subscripts denote partial derivatives, i.e. $\frac{\partial \pi^i}{\partial a_i} = \pi^i_i$. On the reaction function, $\pi^i_i = 0$, so that is a critical point of the isoprofit(or
iso-welfare) curve. Notice that

$$
\frac{d^2 a_j}{da_i^2} = -\frac{\pi_{ij}^i (\pi_{ij}^i)^2 + \pi_{ij}^j (\pi_{ij}^i)^2 - 2\pi_{ij}^i \pi_{ij}^i \pi_{ij}^j}{(\pi_{ij}^i)^3}
$$

$$
= -\frac{\pi_{ij}^i}{\pi_{ij}^j} \text{ at } \pi_{ij}^i = 0
$$

Thus, \( \text{sign} \left( \frac{d^2 a_j}{da_i^2} \right) = \text{sign} \left( \pi_{ij}^i \right) \) at the critical point.

**Appendix B**

**Proof of Lemma 3.1**

From equation 10, we can write the Hessian matrix of second derivatives for centre welfare

$$
H = \begin{bmatrix}
\frac{\partial^2 W}{\partial T_1^2} & \frac{\partial^2 W}{\partial T_1 \partial T_2} \\
\frac{\partial^2 W}{\partial T_2 \partial T_1} & \frac{\partial^2 W}{\partial T_2^2}
\end{bmatrix}
$$

$$
= \begin{bmatrix}
V'' + \gamma F'' k^2 & V'' \\
V'' & V'' + \gamma F'' k^2
\end{bmatrix}
$$

Here \( k = 1 + \frac{\partial \theta_i}{\partial T_i} = \frac{\rho}{\delta + \rho} \). Of course, \( V'' + \gamma F'' k^2 < 0 \) and \( |H| = (V'' + \gamma F'' k^2)^2 - (V'')^2 > 0 \). Thus \( W(.) \) is concave.

Differentiating the FOC with respect to \( \gamma \), we get the following matrix equation

$$
\begin{bmatrix}
V'' + \gamma F'' k^2 & V'' \\
V'' & V'' + \gamma F'' k^2
\end{bmatrix}
\begin{bmatrix}
\frac{dT_1}{d\gamma} \\
\frac{dT_2}{d\gamma}
\end{bmatrix}
= \begin{bmatrix}
-kF' \\
-kF'
\end{bmatrix}
$$

$$
\Rightarrow \frac{dT_i^L}{d\gamma} = -\frac{kF' (\gamma k^2 F'')}{|H|} > 0 \text{ for } i = 1, 2
$$

Thus \( \frac{d\theta_i}{d\gamma} < 0, \frac{d\theta_i^c}{d\gamma} = \theta_i' \left( \frac{dT_i}{d\gamma} \right) < 0 \) and \( \frac{dp_i^c}{d\gamma} = (1 + \theta_i'(T_i)) \left( \frac{dT_i^k}{d\gamma} \right) > 0 \).
Proof of Lemma 3.2

Equation (11) can be written as, say for province 1:

\[
\frac{\partial w_1}{\partial \theta_1} = u'(\theta_1 + T_1) \left(1 + \frac{\partial T_1}{\partial \theta_1}\right) - v'(y_1 - \theta_1) + u'(\theta_1 + T_1) \frac{\partial T_1}{\partial \theta_1} - \beta f''(P) \left(\frac{\partial T_1}{\partial \theta_1} + \frac{\partial T_2}{\partial \theta_1}\right) = 0
\]

Assuming LQ functional forms, \(\frac{\partial T_1}{\partial \theta_1}\) and \(\frac{\partial T_1}{\partial \theta_1}\) are constant numbers. Differentiating above expression with respect to \(\theta_2\), we get

\[
\frac{\partial^2 w_1}{\partial \theta_1 \partial \theta_2} = u'' \frac{\partial T_1}{\partial \theta_2} \left(1 + 2 \frac{\partial T_1}{\partial \theta_1}\right) + \beta f''(P) \left(\frac{\partial T_1}{\partial \theta_1}\right) + 2 \frac{\partial T_2}{\partial \theta_1} + \frac{\partial T_2}{\partial \theta_2} \right)
\]

Notice that the first term is positive, since \(u'' = -\delta < 0\), \(\frac{\partial T_1}{\partial \theta_2} = \frac{\eta}{2\eta + \gamma\phi} > 0\) and \(1 + 2 \frac{\partial T_1}{\partial \theta_1} = 1 - 2 \frac{\eta + \gamma\phi}{2\eta + \gamma\phi} = -\frac{\gamma\phi}{2\eta + \gamma\phi} < 0\). On the other hand, \(f'' = -\lambda < 0\) and sum of \(T_1 + T_2\) falls as \(\theta_1\) or \(\theta_2\) increases. So the second term is definitely negative. If \(\beta\) is large enough, then, even if the first term is positive, the whole expression \(\frac{\phi\gamma}{(2\eta + \gamma\phi)^2} (\delta\eta - \beta\lambda\gamma\phi)\) is negative. Hence \(\theta_1, \theta_2\) are strategic substitute since \(\frac{\partial \theta_1}{\partial \theta_2} = -\frac{\left(\frac{\partial^2 w_1}{\partial \theta_1 \partial \theta_2}\right)}{SOC} < 0.17\)

Proof of Lemma 3.3

To show this, we proceed in two steps. First, we show the (partial) effect of \(\beta\) on \(\theta_i^L\). Second, we demonstrate the total effect of \(\beta\) on \(\theta_i^L\) (consisting of the direct effect as well as the indirect effect via \(\theta_j^L\).

In order to do so, we write the reaction functions (implicitly defined by 11) as \(\theta_i = \Theta^i(\theta_j; \beta)\). Notice that, we have already demonstrated the fact that (lemma 3.1), if \(\beta\) is above a threshold then \(-1 < \frac{\partial \theta_i}{\partial \theta_j} < 0\).

To find the direct effect of \(\beta\) on \(\theta_i\), we need to find \(\frac{\partial \theta_i}{\partial \beta} = -\frac{\left(\frac{\partial^2 w_1}{\partial \theta_1 \partial \beta}\right)}{SOC}\). Given our assumptions, \(\frac{\partial^2 w_1}{\partial \theta_1 \partial \beta} = -f''(P) \left(-\frac{\gamma\phi}{2\eta + \gamma\phi}\right) > 0\), so an increase in \(\beta\) increases \(\theta_i\), if nothing else changes.

17 The SOC is \(\frac{\partial^2 w_1}{\partial \theta_1 \partial \beta} = -\frac{\delta\eta^2}{(2\eta + \gamma\phi)^2} - \rho - \beta\lambda \left(\frac{\gamma\phi}{2\eta + \gamma\phi}\right)^2 < 0\). It can be shown that the magnitude of the slope of the reaction function in \(\theta_i - \theta_j\) space is less than one (Similarly for the other province. That is, the Nash equilibrium is stable.)
To obtain the total effect (because of the ambiguity that higher \( \beta \) increases both \( \theta_i \) and \( \theta_j \), but higher \( \theta_j \) reduces \( \theta_i \)) one has to differentiate the equations \( \theta_i = \Theta_i(\theta_j; \beta) \) and \( \theta_j = \Theta_j(\theta_i; \beta) \) and obtain \( \frac{d\theta_i}{d\beta} \) etc. The resulting matrix equation is

\[
\begin{bmatrix}
1 & -\frac{\partial \Theta_j}{\partial \theta_i}

-\frac{\partial \Theta_i}{\partial \theta_j}
& 1
\end{bmatrix}
\begin{bmatrix}
\frac{d\theta_i}{d\beta}

\frac{d\theta_j}{d\beta}
\end{bmatrix}
= \begin{bmatrix}
\frac{\partial \Theta_i}{\partial \beta}

\frac{\partial \Theta_j}{\partial \beta}
\end{bmatrix}
\]

Here, \( \Delta = \left| \begin{array}{cc}
1 & -\frac{\partial \Theta_j}{\partial \theta_i}

-\frac{\partial \Theta_i}{\partial \theta_j}
& 1
\end{array} \right| = 1 - \left( \frac{\partial \Theta_i}{\partial \theta_j} \right) \left( \frac{\partial \Theta_j}{\partial \theta_i} \right) > 0 \)

Thus,

\[
\frac{d\theta_i}{d\beta} = \frac{\left( \frac{\partial \Theta_i}{\partial \beta} \right) - \left( \frac{\partial \Theta_j}{\partial \beta} \right)}{\Delta} = \frac{\frac{\partial \Theta_i}{\partial \beta} + \frac{\partial \Theta_j}{\partial \beta}}{\Delta}
\]

If we have LQ example (where provinces only differ by income level), \( \frac{\partial \Theta_i}{\partial \beta} = \frac{\partial \Theta_j}{\partial \beta} \). So the numerator is \( \frac{\partial \Theta_i}{\partial \beta} \left( 1 + \frac{\partial \Theta_i}{\partial \theta_j} \right) > 0 \rightarrow \frac{d\theta_i^L}{d\beta} > 0 \). Similarly for \( \frac{d\theta_i^L}{d\beta} \)

Thus, \( \frac{d(\sum T_i^E)}{d\beta} = -\left( \frac{\gamma \phi}{2\eta + \gamma \phi} \right) \frac{d(\sum \theta_i^L)}{d\beta} < 0 \rightarrow \frac{dP_i^E}{d\beta} = -\frac{d(\sum T_i^E)}{d\beta} > 0 \)

and \( \frac{dP_i^L}{d\beta} = \frac{d\theta_i^L}{d\beta} - \left( \frac{\eta + \gamma \phi}{2\eta + \gamma \phi} \right) \frac{d\theta_i^L}{d\beta} + \left( \frac{\eta}{2\eta + \gamma \phi} \right) \frac{d\theta_j^L}{d\beta} \). Since \( \frac{d\theta_j^L}{d\beta} \equiv \frac{d\theta_i^L}{d\beta} \) we have \( \frac{dP_i^L}{d\beta} = 2 \left( \frac{\eta + \gamma \phi}{2\eta + \gamma \phi} \right) \eta \left( \frac{d\theta_i^L}{d\beta} \right) > 0 \). Thus transfers go down, but local taxation rises to compensate such that local project outputs increase.

**Proof of Proposition 4.1**

In this and subsequent proofs, we are omitting other variables \((\theta_j, T_j)\) for notational clarity. Also, the subscripts are dropped: that is \( w^i(\theta_i^E, T_i^E, \theta_j^E) \equiv w^i(\theta_i, T_i^E) \) (subscripts are dropped). Here, the superscript \( E \) \(^{18}T_j \) being a parameter in the equilibrium
stands for different equilibria, e.g. Nash or Stackelberg. Similarly for the centre.

Second part of the proposition is evident: so only the first part is proved. The proof follows Dowrick (1986). Notice that, we need to show that the Centre is better off as a Stackelberg follower than leader.

**Proof.** The proof proceeds in two stages. In the following figure, we have drawn reaction function of the centre and a Stackelberg point B \((\theta_L, T_F)\) such that province is the leader (the iso-welfare curve is not necessary).

![A Stackelberg Follower Point of Province](image)

Fig A1: A Stackelberg Follower Point of Province

First, we show that the reaction function of the province, \(\theta = \theta (T)\) must be below B, i.e. \(\theta (T_F) < \theta_L\).

\(^{19}\)The proof does not depend on linear quadratic assumption.
Suppose not. Then \( \theta_M = \theta(T_F) > \theta_L \). Thus we have, for the province, \( w(\theta_M, T_F) > w(\theta_L, T_F) \) (by the definition of reaction function). Let, \( T'_F \) be the best response to \( \theta_M \), that is, \( T'_F = T(\theta_M) \). But, then since \( w_T < 0 \), we have \( w(\theta_M, T_F) < w(\theta_M, T'_F) \). Combining these inequalities, we get \( w(\theta_M, T'_F) > w(\theta_m, T_F) > w(\theta_L, T_F) \). But then, \( (\theta_L, T_F) \) cannot be the Stackelberg leadership point of the province on the reaction function of centre.

Second, \( \theta = \theta(T) \) cannot pass through the Stackelberg leadership point B. Notice that the isoprofit curve of the province must have zero slope on \( \theta = \theta(T) \). For simultaneous tangency on \( T = T(\theta) \) a critical point of \( \theta = \theta(T) \), the reaction function \( T = T(\theta) \) must be positively sloped. But this case is ruled out either. Thus, \( \theta = \theta(T) \) must be below B, the Stackelberg leadership point of the province. So, \( \theta_M < \theta_L \).
Fig A3: Centre Prefers to be Follower.

Note that, $W(\theta_L, T_F) > W(\theta_M, T_F)$, since $W_\theta > 0$. But, $(\theta_M, T_F)$ is one of the set of points which the centre can choose as a Stackelberg leader. Therefore, centre must prefer to be a Stackelberg follower if $W_\theta > 0$ and $w_T < 0$.

Proof of Proposition 5.1 (Part i)

As before, we are focussing on the interaction between one province and the corresponding transfer.

**Proof.** Comparing provincial Nash and Leadership position, we have

$$w(\theta^L, T^F(\theta^L)) \geq w(\theta^N, T^N)$$

by definition of Nash equilibrium and Stackelberg leadership.

When province is follower in a Stackelberg game or under Nash protocol, equilibrium occurs on provincial reaction function. Thus, we must have, by the definition of reaction function,

$$\frac{\partial w(\theta^N, T^N)}{\partial \theta} = \frac{\partial w(\theta^F, T^L)}{\partial \theta} = 0$$

B2
Given $w_T < 0$

$$\theta^N > \theta^F \iff T^N < T^L \quad \text{(B3)}$$

Again, by definition of Nash equilibrium:

$$w(\theta^N, T^N) \geq w(\theta^L, T^N)$$

Suppose $T^N > T^F$. Then

$$w(\theta^N, T^N) \geq w(\theta^L, T^N) > w(\theta^L, T^F)$$

The second inequality follows from the fact that $w_T > 0$. But this contradicts with the definition of Stackelberg leadership. Therefore, we must have $T^N < T^F$. Notice that $T^N$ and $T^F$ are on the same (downward sloping) central reaction function. The $\theta^N > \theta^L$. Similarly, for the centre ($W_{T\theta} < 0$ and $W_{\theta} > 0$), we must have $\theta^F > \theta^N$. But $\theta^N$ and $\theta^F$ are two points on the (downward sloping) provincial reaction function. So we must have $T^L < T^N$. Combining these observations, we have result 5.1 (i). 

Proof of Proposition 5.1 (Part ii)

**Proof.** For part (ii), notice that $\beta$ is high, so that $w_T < 0$. Applying the same methodology as in 5.1 (part i), we have $T^N > T^F$, i.e. $\theta^N < \theta^L$. At the same time, $\theta^F > \theta^N$ i.e. $T^L < T^N$. That is, we have $(\theta^F, \theta^L) > \theta^N$ and $(T^F, T^L) < T^N$. However, the relative magnitudes of various leadership positions with the follower position is not known.

Let us assume $T^L > T^F$.

We compare the first order conditions of the equilibrium of the centre. We already know that, when centre is the follower, as well as in Nash outcome

$$\frac{\partial W(\theta^L, T^F)}{\partial T} = \frac{\partial W(\theta^N, T^N)}{\partial T} = 0$$

We compare this with the case when centre is the leader. It solves the problem

$$\max_T W(T, \theta(T)) = 0$$

26
The FOC yields
\[
\frac{\partial W(\theta^F, T^L)}{\partial T} + W_\theta * \frac{\partial \theta}{\partial T} = 0
\]
Note that \( \frac{\partial \theta}{\partial T} = \frac{-w_{T\theta}}{w_\theta} < 0 \). Given \( W_\theta > 0 \), we must have \( \frac{\partial W(\theta^F, T^L)}{\partial T} > 0 \). Thus
\[
\frac{\partial W(\theta^F, T^L)}{\partial T} > \frac{\partial W(\theta^L, T^F)}{\partial T} = \frac{\partial W(\theta^N, T^N)}{\partial T}
\]
If \( T^L > T^F \), then \( \theta^F < \theta^L \).
Notice \( \frac{\partial W(\theta^L, T^F)}{\partial T} > \frac{\partial W(\theta^L, T^L)}{\partial T} \) since MU falls with \( T \) and \( T^L > T^F \).
The second \( \frac{\partial W(\theta^L, T^L)}{\partial T} > \frac{\partial W(\theta^F, T^L)}{\partial T} \) since MU falls with \( \theta \) (\( W_{T\theta} < 0 \)) and \( \theta^L > \theta^F \). Combining these two statements, \( \frac{\partial W(\theta^L, T^F)}{\partial T} > \frac{\partial W(\theta^F, T^L)}{\partial T} \) which is a contradiction.
Thus \( T^F > T^L > T^N \).
Note, however, this inequality does not tell us anything about relative values of \( \theta^L \) and \( \theta^F \) since these are on two separate reaction functions.

We have already noted
\[
\frac{\partial w(\theta^F, T^L)}{\partial \theta} = \frac{\partial w(\theta^N, T^N)}{\partial \theta} = 0
\]
When province \( i \) is leader, it maximises
\[
\max_{\theta} w(\theta_i, T_i(\theta, .), T_j(\theta, .))
\]
FOC is
\[
w_\theta + \left[ w_{T_i} * \frac{\partial T_i}{\partial \theta_i} + w_{T_j} * \frac{\partial T_j}{\partial \theta_i} \right] = 0
\]
Notice that, \( w_{T_i} < 0 \) and \( \frac{\partial T_i}{\partial \theta_i} < 0 \). On the other hand, \( w_{T_j} < 0 \) and \( \frac{\partial T_j}{\partial \theta_j} > 0 \). (Note: \( w_{T_i} = u - \beta f' \) and \( w_{T_j} = -\beta f' \)). Using the LQ specification, \( \frac{\partial T_i}{\partial \theta_i} = -\frac{\eta + \gamma \phi}{2\eta + \gamma \phi} \) and \( \frac{\partial T_j}{\partial \theta_j} = \frac{\eta}{2\eta + \gamma \phi} \). Thus the terms within
square brackets can be written as

\[ w_{T_1} \frac{\partial T_1}{\partial \theta_1} + w_{T_2} \frac{\partial T_2}{\partial \theta_1} = -\left( u' - \beta f' \right) \frac{\eta + \gamma \phi}{2\eta + \gamma \phi} + \frac{\eta}{2\eta + \gamma \phi}(-\beta f') \]

\[ = \beta f' \left( \frac{\eta}{2\eta + \gamma \phi} \right) - u' \left( \frac{\eta + \gamma \phi}{2\eta + \gamma \phi} \right) \]

We already know that $\beta$ is sufficiently large such that $\beta f' > u'$. We need to impose a mildly stringent restriction on $\beta$, i.e. $\beta f' > u' \left( 1 + \frac{\gamma \phi}{\eta} \right)$ such that expressions under square brackets is positive and

\[ \frac{\partial w(\theta^L, T^F)}{\partial \theta} < \frac{\partial w(\theta^F, T^L)}{\partial \theta} = \frac{\partial w(\theta^N, T^N)}{\partial \theta} \]

A comparison between the first two terms imply that one cannot rank $\theta^L$ and $\theta^F$ from the condition stated above. However, if the isowelfare curve of the province cuts the reaction function of the centre at the point $\left( \theta^F, \tilde{T} = T(\theta^F) \right)$, then the tangency (which defines $\theta^L$) between provincial isoprofit curve and central reaction function occurs at a higher point, that is $\theta^L > \theta^F$. The possibility is shown in the following diagram.
Figure A4: Condition for $\theta^L > \theta^F$

Slope of the provincial isoprofit curve $\frac{\partial \theta}{\partial t}|_{(\theta^F, T^*)} = -\frac{u' - \beta f'}{u' - v'}$, while that of central reaction function in the $\theta_i - T_i$ plane is $A_i$ (e.g. for LQ assumption, it is $\frac{2\eta + \gamma \phi}{\eta + \gamma \phi}$). So we need $\frac{u' - \beta f'}{u' - v'}|_{(\theta^F, T^*)} > A_i$. Since the point $(\theta^F, T^*)$ is above the reaction function of the province, we must have $u' - v' < 0$. The inequality then suggests $\beta > \beta = \frac{u' - A_i * (u' - v')}{f'}|_{(\theta^F, T)}$ is required for $\theta^L > \theta^F > \theta^N$. This is also partially corroborated by lemma 3.3.

It is easy to (but tedious) figure out $\dot{\beta}$ for the LQ example. As we know, $T^L_i = \frac{M \eta - 1 + \alpha \gamma - (\eta + \alpha \gamma \phi) y_i + \eta y_j}{2\eta + \alpha \gamma \phi} \to \theta^F_i = \alpha y_i - (1 - \alpha) T^L_i$, where $\alpha = \frac{\rho}{\rho + \delta}$. This, in turn, implies that

$$T^*_i = \frac{\gamma + M \eta - 1}{2\eta + \gamma \phi} - \frac{\eta + \gamma \phi}{2\eta + \gamma \phi} \theta^F_i + \frac{\eta}{2\eta + \gamma \phi} \theta^F_i$$

$$\dot{p}_i = \theta^F_i + T^*_i$$

$$\dot{P} = \frac{M \gamma \phi + 2(1 - \gamma)}{2\eta + \gamma \phi} + \frac{\gamma \phi}{2\eta + \gamma \phi} (\theta^F_i + \theta^F_i)$$

29
From here, we can calculate $u' = 1 - \delta \hat{p}_i$, $v' = 1 - \rho (y_i - \theta_i^F)$ and $f' = -1 + \lambda \left( \hat{P} \right)$. ■
